Description

Method for controlling the transmission of data

The invention relates to a method for controlling the transmission of data in accordance with the preamble of claim 1.

From the steadily converging communications and information technologies, networks are known, such as for example the "local area network" LAN, with a multitude of stations designed for data transmission, in which the transmission of data is effected by conduction, i.e. over wires which connect the stations, while for a local network constructed in accordance with the IEEE 820.11 standard (wireless local area network, WLAN) the transmission is realized by wireless means, i.e. over a radio link, with a hybrid network of stations which are linked in via wires or radio links also being permissible in the case of a WLAN.

Stations which are connected to decentralized and non-deterministic networks of this type mostly have applications implemented on them, or in some cases permanently installed in them, which cover various services and which - depending on the nature of the station - can differ from one station to another. Thus, the convergence of networks in the information and communication technologies has led to the development of networks and services from the transmission of "non-time-critical" data, such as arises with a file transfer or the transmission of e-mails, through to networks with "time-critical" data, such as for example the transmission of streaming media, speech data ("Voice over IP, VoIP) and video conferences, whereby one reason for these latter services being so time-critical is that delays and/or loss of data are immediately detected, i.e. heard

or seen, by a user, and for this reason they call for the associated data to be transmitted as nearly as possible in real-time.

For this reason, a so-called quality of service has been introduced in the IEEE802.11 standard. The term quality of service (QoS) is to be understood as covering all methods which influence the data flows in LANs and WANs in such a way that the service is prioritized or arrives at the receiver with a specified quality. A prioritization approach provides for a higher priority being assigned to time-critical services, such as video-conferencing, than to non-time-critical ones, whereby data packets with a higher priority, as determined by the prioritization, are transmitted preferentially.

A disadvantage in networks of this type is that each of the stations, at which data is ready to be transmitted, has the same right to occupy the transmission medium if the data to be sent has the same priority. As the number of transmitting stations increases, the capacity of the medium available for each station decreases steadily so that it is no longer possible, in particular, to adhere to quality of service parameters such as the data transmission rate and delay. The ultimate result of this, especially in connection with the provision of time-critical services such as voice or video stream transmission, is that none of these services can be handled to the satisfaction of the service user.

The object underlying the invention is to specify a method which makes it possible to raise the user satisfaction in the provision, in particular, of highly prioritized services.

This object is achieved starting from the characterizing clause of claim 1 by its characteristic features.

For the method in accordance with the invention for controlling the transmission of data, via data links which are assigned to different applications, over a transmission medium in a network, in particular a local one, with at least two stations designed for data transmission, where the applications are assigned different priorities together with different parameters to identify a quality of service, the establishment by a first station of a new data link, assigned to a first application, is restricted as a function of the available free channel capacity on the transmission medium together with the occupancy of the transmission medium by existing data links, for which the applications have a priority corresponding to that of the first application.

The method in accordance with the invention ensures that existing links, in particular those for applications with high quality of service requirements, such as for example video or voice data transmission, are not detrimentally affected by newly-arising connection wishes from applications with the same priority class. In this way it is possible to ensure that the quality of the services which have already been offered remains largely constant.

If, when there is a requirement for the establishment of a new data link, this data link is set up by the first station without regard for the current utilization, while the transmission medium is occupied by data links assigned to an application with at least a second priority corresponding to that of the first application, at least one of the second stations which are maintaining these links signals in such a way that on the

transmission medium a message is communicated with the highest priority to the first station and, after it has received the message, the first station suspends the new data link, at least temporarily, then the determination of the current resource usage is simplified, because this is already indicated by those stations which are already active. This development of the invention thus permits externally initiated occupancy control.

An algorithm which is very simple to implement results if, when there is a request for the establishment of a new data link, the first station determines whether a measure of the available free channel capacity corresponds to a measure of the necessary channel capacity given by the parameters of the first application, with any data traffic which is assigned to applications with lower priority than the priority of the first application being regarded, in the context of the determination procedure, as free channel capacity. If the result of the determination is positive, the data link is set up, or if the result of the determination is negative the establishment of the data link is suspended, at least temporarily.

In doing this, the assessment of the free channel capacity should preferably be based on a threshold decision. I.e. the channel capacity is regarded as free up to the point where a threshold is reached. Here, the threshold corresponds in general to a previously defined percentage level of data traffic which is assigned to applications with lower priority. In this connection, a threshold of this type offers the advantage that, if structured as a parameter, it can easily be modified appropriately for the conditions in the system.

Further details and advantages of the invention will be explained by reference to the exemplary embodiment shown in the single figure, in which;

FIGURE shows a typical arrangement (scenario) of a wireless local network which makes use of the method in accordance with the invention.

The figure shows as a model six stations MT1..MT6 in a wireless network which makes use of the method in accordance with the invention.

In this scenario it is assumed that between a first station MT1 and a second station MT2, and between a third station MT3 and a fourth station MT4, data is transmitted wirelessly (continuous lines), i.e. over a defined air interface, with the data stream which this involves not fully using up the channel capacity of the air interface, so that the quality of service, required for the services provided by the data transmission, for example video and voice data transmission, can be adhered to without loss.

Starting from this initial situation, three possible more advanced scenarios are to be discussed.

Scenario 1: A fifth station MT5 wants to transmit data to a sixth station MT6, until now inactive.

Scenario 2: The fifth station MT5 wants to transmit data to a station which is already receiving high-priority data, e.g. video-conferencing, such as for example the second station MT2.

Scenario 3: The fifth station MT5 wants to transmit data to a station which is already transmitting data.

For the following discussion, it is further assumed that the channel capacity of the air interface would not be sufficient for the data arising from the fifth station without a loss of quality on the links which already exist, and that the stations MT2, MT4 and MT6 do not lie within the radio reach of the station MT5.

In such a situation it is possible that, for an existing wish by the fifth station MT5 to transmit data, an internal data buffer of the first station MT1 and an internal data buffer of the fourth station MT4 will no longer be emptied, and an overflow would be threatened.

In the case of scenario 1, when a data overflow was detected, the fifth station MT5 would in accordance with the invention be requested by the fourth station MT4 to halt its data service for a period x . If, on expiry of this period x , the fifth station MT5 were to cause a data overflow during its renewed attempt to transmit the data, then in accordance with the invention a request would again be made from the fourth station MT4 for the service to be postponed for a further period x , this time increased by a discrete value.

If a buffer overflow arises at the first station MT1, it will report this to the second station MT2 which, for its part, passes on the request for suspension of the data transmission for a period x to the fifth station MT5.

In the case of scenario 2 and scenario 3 it is possible, for example, to effect the rejection of the fifth station MT5 im-

plicitly, when a capacity bottleneck is detected, by a refusal of the transmit permission, e.g. by refusing the CTS (clear to send), where in the case of scenario 2 this requires in turn a message from the first station MT1 to the second station MT2 about an internal buffer overflow.
